At Blowing Rock, N. C., where it is not uncommon, I have always found it along the mountain roads on the banks. It is 5-10 cm. high, the cap from 3-8 cm. broad, and the stem 6-10 mm. in thickness. The pileus is convex, then expanded, plane or convex, and when mature more or less top-shaped because it is so thick at the middle. In age the surface of the cap often becomes cracked into small areas, showing the yellow flesh in the cracks. The flesh is yellowish and the surface is dry. The gills are not very distant, they are stout, chrome yellow to lemon yellow, and strongly decurrent. A few of them are forked toward the base, and the surface and the space between them are marked by anastomosing veins forming a reticulum suggestive of the hymenium of the Polyporaceae. This character is not evident without the use of a hand lens. The surface of the gills as well as the edges is provided with clavate cystidia which are filled with a yellow pigment, giving to the gills the bright yellow color so characteristic. These cystidia extend above the basidia, and the ends are rounded so that sometimes they appear capitate. The yellow color is not confined to the cystidia, for the sub-hymenium is also colored in a similar way. The spores are yellowish, oblong to elliptical or spindle-shaped, and measure 8-12 x 3-5 μ . The stem is the same color as the pileus, but paler, and more yellow at the base. It is marked with numerous minute dots of a darker color than the ground color, formed of numerous small erect tufts of mycelium. Figure 160 is from
